Because Photoshop is a powerful program, those images that you create with it cannot be deemed free of quality loss. Therefore, when you shoot and edit (or have someone else do it for you) a picture, you need to be aware of any problems that you may have missed when you edited the image later in Photoshop. Another good reason to let someone do the image editing is to avoid making mistakes, because you don't know as much as a professional.

Metasoma decoration Metasoma decoration is a type of animal body painting found in the New World, especially in the Panama area. It is associated with the Cuello and Inga species in particular. History Metasoma decoration was most likely introduced into northern South America by humans. It is found in all three major subparts of the continent as far north as the Tumbes, as far east as Costa Rica, and as far south as Chile and Argentina. Structure The metasoma, or last segments of the body, of the insects that display this type of body decoration are brightly colored. The abdomen is sometimes monochrome, but the overall body often stands out in stark contrast to the background coloration. Although the gills are not drawn or raised as in some other forms of body painting, they are often more brightly colored than the rest of the body, even if they are not painted as brightly as the rest of the metasoma. This often results in a striped or spotted appearance of the gills, along with the rest of the insect. Use The metasoma of these insects have many different functions. The main one is probably thermoregulation, especially in colder climates. In the daytime, the highly colored body helps to reflect heat back into the insect's body. At night, the bright colors and patterns allow the insect to blend in with its background, allowing it to sneak up on its prey. Another important role of the metasoma is sexually suggestive. Both males and females of these insects are highly sexually dimorphic. The males are usually brightly colored, especially with blue and red patterns. This tends to be especially obvious in the abdominal and genital regions, and has been used to enhance mating displays. The females have less extreme sexual dimorphism. The lower abdomen tends to be less brightly colored and more monochrome. The upper torso and the face, however, often has more brightly colored patterns. These patterns are used to indicate the identity of the female, and are often used in conjunction with their faces to advertise age, sexual maturation, and even dominance. Although the structures involved in metasoma decoration are fairly large, the overall size of the insect is relatively small. The body size of the insect is often exaggerated to suggest youth and virility. The structure involved in metasoma decoration is unique to animals in the New World. While some very simple markings have been found

Receptor-mediated transport is a central issue in biology in this generation. Genetically defined substrates or ligands which are specific for particular receptors may be used for initial screening and primary isolation of receptor proteins. Receptors are found on all mammalian cells, and their biologic function is generally understood. For example, in bacteria and parasites, such as *Plasmodium falciparum* and *Schistosoma mansoni*, the receptors for human transferrin (Tf) and its receptor on erythrocytes, respectively, have been studied. The biologic function of such receptors is still not clear; nevertheless, such receptors may be useful as targets for chemotherapeutic agents. Blood-feeding and merozoite invasion of host cells by the malaria parasite *Plasmodium falciparum* is probably mediated by a class of receptors known as invasion-associated erythrocyte surface antigens (IASAs). The molecular identity of these receptors and their ligands remains unknown. Previous studies have identified two erythrocyte membrane-bound proteins that cross-react with IASAs, namely, glycophorin A (GPA) and Band 3, a erythrocyte membrane protein. In an effort to identify additional receptors on erythrocytes, Meraldi et al., supra, utilized a monoclonal antibody directed against the receptor for the pathogenic protein

of *Babesia bovis*, BoT9/81. A ligand of BoT9/81 is a erythrocyte membrane protein, designated as BoT9-3. Although BoT9/81 and BoT9-3 specifically bind to the erythrocyte membrane, the receptor proteins are believed to be found in additional subcellular structures, presumably because of the apparent multimeric nature of BoT9/81 and BoT9-3. The antigen p32 (Meraldi, 1994) and the protein TEP1 (Kimura, 1994) have recently been isolated, cloned and sequenced by one of the present inventors (Murali Rao). U.S. Pat. No. 5,653,987 and U.S. Pat. No. 5,856,088 disclose the expression of the TEP1 polypeptide and the p32 protein in *E. coli*, and the use of the purified recombinant polypeptides to detect the invasion ligand-receptor
